Abstract

There are many fundamental issues in regional and urban economics that hinge on worker skills. This paper builds on psychological approaches to learning to characterize the role of education and agglomeration in the skill development process. While the standard approach of equating skill to worker education can be useful, there are important aspects of skill that are missed. Using a measure of skill derived from hedonic attribution, the paper explores the geographic distribution of worker traits, intelligences, and skills and considers the roles of urbanization and education in the skill development process.

JEL Codes: R30, J24

1. INTRODUCTION

There are many fundamental issues in regional and urban economics that hinge on worker skills. A city's prosperity and growth depend crucially on its ability to attract productive workers, match them appropriately to jobs, and further develop their skills. The importance of skills goes back to the beginnings of urban economics, including Marshall (1890), Vernon (1960), and Jacobs (1969).

Skills are central to a number of current lines of research as well, especially research on agglomeration and labor markets. Glaeser and Mare (2001) document a substantial urban wage premium, and show that a significant fraction of it results from the sorting of high-skill workers into large cities. The importance of this selection effect is further reinforced by the panel estimates of Combes, Duranton, and Gobillon (2008). Regarding how the benefits of agglomeration accrue to workers of different skill levels, Wheeler (2001) finds that more educated workers enjoy a larger premium across a range of occupations, while Adamson et al (2004) and Lee (2008) find the opposite. Regarding the external effects of local human capital, Rauch (1993) documents a positive relationship between the local level of human capital and wage. These human capital spillovers are considered further by Moretti (2004a, 2004b), Ciccone and Peri (2006), and Rosenthal and Strange (2008). A relationship between a city's level of human capital and urban growth is found in Simon and Nardinelli (2002), Florida (2002), and Glaeser and Shapiro (2003). A relationship between local skill levels and innovation is found in Audretsch and Feldman (1996), while Andersson et al (2009) identify a relationship between the presence of a local university and innovation and productivity. Finally, agglomeration appears to impact the movement of skills across activities through job turnover (Freedman, 2008). In sum, skills matter.

In the large literature on skills in cities and regions, it is common to equate a worker's skill to the worker's education level. By this metric, as long as they all graduate, all of the students in a class are equally skilled. This does not really capture what Marshall, Jacobs, and Vernon had in mind. This is also a quite different approach than is taken in developmental psychology, a field in large part dedicated to understanding learning.

In this paper, we build on psychological approaches to learning to analyze the role of education and agglomeration in the skill development process. This literature is discussed in detail in Section 2. Very roughly, these psychological approaches posit that individual traits and intelligences interact with the environment to produce skills. Traits are stable personal characteristics (i.e., temperament and personality). Traits are determined by genetic endowment and early environment. Intelligences are defined as the ability to process contents of the world, including, for example, the ability to process words and logical relationships (verbal vs. propositional intelligence) and the ability to arrange and rotate objects in space (spatial intelligence). Intelligences are thought to be somewhat more plastic than are traits, at least early in life. Like traits, intelligences are also produced by genetic endowment and

environment, with traits also impacting the development of the abilities to process world content. Early acquisition of these abilities can, in addition, facilitate the further development of intelligences. Finally, skills are behavioral manifestations of intelligences and traits. For our purposes we will focus on the marketable or productive aspects of intelligences and traits. For example, creative thinking and flexible planning are skills that can be developed by people that have the necessary traits and intelligences and are exposed to the right environment. Education is an important part of the environment to which individuals are exposed. Urbanization is another one.

In this approach, education and skill are not equivalent. Education is instead part of the process determining a multi-dimensional package of skills. Urban economists are manifestly aware of the limitations of the skill-equals-education approach, as is apparent from the many strategies employed to deal with unobserved heterogeneity in worker skill. These strategies are often indirect, however. Sometimes, they involve including controls for worker traits that are related to skills. Sometimes, the approaches involve using fixed effects. Both approaches are appropriate ways to deal with the econometric problems associated with unobserved skill heterogeneity. Neither sheds light directly on the relationship between worker skills and agglomeration.

We therefore propose, as an alternative, a direct measure of skills. It involves the construction of skill measures from the relatively new O-NET and from its predecessor, the Dictionary of Occupational Titles (DOT). These are designed to help a job searcher identify the skill requirements of jobs in order to plan a career. If the hedonic labor market equilibrium is frictionless in matching worker skills to jobs, then O-NET and the DOT can be used in reverse: as ways to identify the skills possessed by workers holding various jobs. An education measure identifies all graduating students as being equally skilled. This hedonic attribution measure separates graduates according to the positions that they fill after graduation.¹ We merge these data with the panel data from the National Longitudinal Survey of Youth (NLSY79) to obtain workers' characteristics, including a number of measures of traits and intelligences.

This hedonic attribution approach has been employed previously by Bacolod, Blum, and Strange (2009a), who consider how urbanization impacts the hedonic prices of different skills and their spatial allocation. The approach is also employed in Bacolod, Blum, and Strange (2009b), who focus on the

¹ Elvery (2009) follows a related approach of using the mean wage in medium sized city in a worker's occupation to proxy for the worker's skill. Another related approach is taken by Audretsch and Feldman (1996), who characterize local skills by the employment in professional and managerial occupations, plus craftspeople. Yet another parallel is found in the work of Agrawal-Kapur-McHale (2008) and Agrawal-Kapur-McHale (2009), who effectively identify skill through past innovative activity of "inventors."

"soft" skills associated with interaction. This approach has also been used by Scott (2008) and Scott and Mantegna (2009), who also consider, among other things, the spatial allocation of skills.²

Making use of the DOT skill attribution and the new variables from the NLSY, we carry out an econometric analysis of the role of agglomeration in the manifestation of traits and abilities as marketable skills. The analysis employs several variables that characterize worker traits and intelligences that are new to the urban and regional literatures. It explicitly considers education and urbanization as choice variables in the process of skill formation.³ The key conclusion of this part of the paper is that urbanization, like education, has a positive relationship with cognitive and people skills. Urbanization is negatively correlated with motor skills. Therefore, there is not a monotonic mapping between the multidimensional vector of skills we use and the measure of worker's education, making it difficult to justify the use of education as a proxy for skills. Furthermore, there is strong evidence of selection, where highly capable workers are more likely to move and choose larger cities.

The rest of the paper is organized as follows. Section 2 lays out the skill development framework around which our analysis is constructed. Section 3 discusses the data that is available for considering abilities, traits, and skills. Section 4 makes use of some of these data sources to consider the impact of urbanization on the skill development process. Section 5 concludes.

2. FRAMEWORK

Psychological Approaches to Learning

This section will set out a framework that relates a worker's traits and intelligences to skills. Education will influence the relationship, and so will urbanization. The section's analysis will draw significantly from research in psychology.

Psychologists conceive of skills as arising from the traits and intelligences of workers, with additional influence coming from genetic endowment and environment. A personality trait is defined as an enduring personal characteristic that reveals itself in a particular pattern of behavior in a variety of situations (Carlson et al, 2005).⁴ There are many personal characteristics that have been identified as personality traits in this sense. Psychologists have used factor analysis to create a small number of linear combinations of them to capture the most important aspects of personality traits. For instance, Eysenck (1970), proposes a three factor model, extroversion, neuroticism, and psychoticism, while Cattell's (1946)

²Recent work on skills in labor economics has also acknowledged that skills are multi-dimensional, and thus not simply identical to education (Bowles et al (2001), Autor et al (2003), and Heckman et al (2006)).

³ This means that they can be correlated for various reasons . For instance, if urbanization affects the process through which individuals acquire traits and intelligences, and traits and intelligences affect the individual's decision to acquire education, urbanization can impact skills via education.

⁴ We will focus primarily on personality traits.

analysis includes sixteen factors. The set of personality traits most frequently used by psychologists include five factors: openness (O), conscientiousness (C), extroversion (E), agreeableness (A), neuroticism (N) (see Costa and McCrae, 1998) and it is commonly referred as the big five.⁵

Personality traits have been shown to be heritable (see Bouchard and Hur, 1998) in studies that compare the personalities of identical and fraternal twins, twins that were raised together and twins that were raised apart, and biological and adopted relatives. Zuckerman (1991) concludes that between 50% and 70% of the individual variability in extroversion, neuroticism, and psychoticism is due to heredity. The same study compares identical twins raised together and separately to assess whether differences in the environment can account for the remaining 30-50%. It finds that the personalities of twins raised together are no more similar than the personalities of the ones raised apart. This suggests that it is not the general environment that accounts for the remaining 30-50% in personality differences, but rather individual-specific relationships, possibly within the family.

All this evidence reinforces the notion that personality traits are very stable, at least over one's adult life. Indeed, Costa and McCrae (1988) show that after the age of 30 individuals' personalities basically do not change further. Before that, there is some evidence of personality changes, such as individuals becoming less emotional and thrill-seeking during their twenties, but there is little indication that the environment can have a big effect on these changes.⁶

Intelligence is defined in different ways by different psychologists. Carlson et al (2005), for example, writes that "Most psychologists would define intelligence as a person's ability to learn and remember information, to recognize concepts and their relations, and to apply the information to their own behavior in an adaptive way." Gardner (1999), on the other hand, defines intelligence as the ability to process the contents of the world. The existence of different definitions for intelligence reflects, in part, different beliefs on whether there is a single intelligence or if there are multiple more or less independent forms of intellectual ability. Initial theories of intelligence conceived of a general form of intelligence, often referred to as the g-factor, which has been measured by different intelligence tests such as IQ tests. More recently, psychologists have conceived of multiple types of intelligence, as individuals may have different abilities to process distinct aspects of the world. Gardner (1983), for instance, uses biological isolation, i.e., the identification of distinct areas of the brain associated with various circumstances, to conclude that there are eight types of intelligences, including logical-mathematical intelligence, linguistic intelligence, spatial intelligence, intrapersonal intelligence, and interpersonal

⁵Thurstone (1934) seems to be the first published reference to the five factor model.

⁶ See Caspi et al (2005) and Rantanen (2007) for a discussion on when in adulthood personality traits become rank-order stable. Even if personality traits change in adulthood, there is little evidence that the environment affects such changes.

intelligence. He then goes on to identify the specific skills and activities that individuals with large amounts of each type of intelligence can perform and the occupations they are likely to sort into.

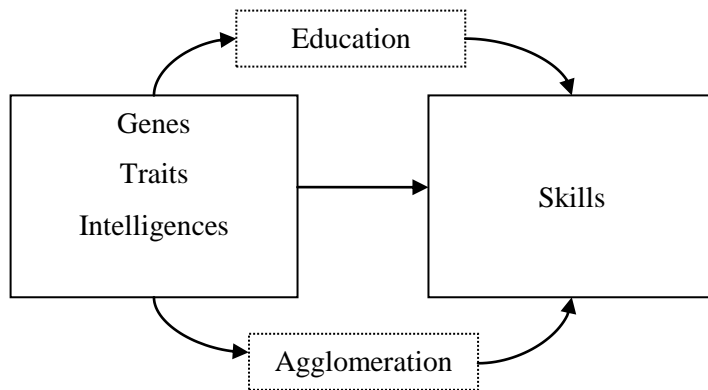

The roles of heredity and environment on intelligences are also controversial. Neisser et al (1996) summarize the evidence on the heritability of IQ and finds that about 45% of the variation in IQ scores in children is explained by genetic factors while for individuals at late adolescence this number goes up to 75%. Studies of the effects of special programs, such as the Head Start Program, show that they are successful in raising children's IQ scores while they are participating in the program, but these effects are not long-lasting. However, the same studies find that these programs have a significant and lasting effect on other measures, such as career paths, grade retention, and the probability of keeping a job. This has been suggested as evidence on the effects of these programs on non-cognitive types of intelligences. Even if all or some intelligences can be affected by the environment, it is important to understand when at an individual's life this can happen. Jones and Bayley (1941) applied IQ tests on children annually during their childhood and adolescence. Scores at the ages of 18 and 6 were correlated at 0.77 while scores at the ages 18 and 12 were correlated at 0.89. When successive years were averaged to eliminate short run fluctuations, the correlations were even higher. More recent studies confirm these findings (e.g., Moffitt et al, 1993).

This evidence sheds light on what kind of influence the urban environment can have. It seems to suggest little scope for the urban environment to affect cognitive intelligence, at least in adults. It suggests more potential scope for an urban influence on skills, which we define as behavior manifestations of traits and intelligences, with other environmental factors potentially affecting the process. We will consider this exactly later in the paper.

Skill Formation

Because of the lack of detailed data on individuals' traits and intelligences in large datasets, we will not be able to make much of the trait/intelligence distinction. We will instead focus on how agglomeration and education impact how traits and intelligences together are manifested as skills. Figure 1 summarizes this approach.

Figure 1. Skill Formation

As drawn, Figure 1 shows that both education and agglomeration influence the development / manifestation of skills. The role of education has been central to psychological approaches to skill development since the birth of psychology as a field. Binet's intelligence tests were designed explicitly to predict educational outcomes. The ensuing Stanford research and the notion of an intelligence quotient had a similar motivation. Although education is potentially important in developing traits and intelligences, it may also be important in the manifestation of abilities and traits as skills. For instance, education allows someone with mathematical intelligence to develop skills in engineering. It may also allow a worker with spatial intelligence to develop the skill required to engage in precision manufacturing.

It is well-known, of course, that formal education is not the only way that children develop abilities and traits into skills. There are numerous informal learning mechanisms. Urban and regional economists have long been interested in the way that agglomeration -- both in cities and in industry clusters -- contributes to learning of both the formal and informal varieties. The possible impact of a worker's urban status on skill development is illustrated at the bottom of Figure 1. It is important to note that locations, like education, are chosen, and so may depend on worker traits and abilities. We will return to this issue below.

Skills and Agglomeration

As noted in the Introduction, skills pertain to a number of important issues in urban and regional economics. One of these is the role of skill in the generation of and benefit from agglomeration economies, as manifested in the urban wage premium. This is depicted below in Figure 2.

Figure 2. Traits, Intelligences, Skills, and Wages

As depicted in the figure, traits and intelligences lead to skills, with intermediation by education and agglomeration. Skills lead to wages, again impacted by agglomeration.

More formally, Figure 2 suggests a simple model of skill development that operationalizes the ideas we have been discussing. The model builds loosely on Cunha and Heckman (2007). The key components of the model are as follows. Workers have primitive characteristics, both traits and intelligences. Let t give the initial vector. Skill development depends on initial traits and intelligences as well as on education and possibly local agglomeration. Let this relationship be given the vector-valued function $s = h(t, z, n)$ giving the vector of skills as a function of traits, abilities, education, and city population.⁷ Skills impact outcomes. In addition to impacting the development of skills from traits and intelligences, urbanization also influences the application of skills to production. It thus impacts worker wages. Let this relationship be $w = q(s, n)$, where wage is an increasing function of a vector of worker skills s and n .

This simple model illuminates specification issues in the estimation of the urban wage premium. Specifically, one can justify estimating models of the $q(s, n)$ relationship, but this requires data on skills. One could also justify estimating reduced form models $q(h(t, z, n), n)$. This would not require data on skills, but it would require data on traits. Estimating models with only education is potentially problematic. It is also important to recognize that theory suggests that urbanization has impacts in two places, both in skill development and in skill deployment in production. The reduced form model would present estimates of the net effect of both impacts.

To consider this relationship in more detail, we begin with the case of unique intelligence and skill. Specifically, we suppose for now that there is one characteristic, and this one characteristic predicts

⁷ We treat n as equaling city population throughout this discussion. There is no reason, however, that n could not instead measure instead the local activity in a worker's industry (Marshallian localization).

education, the one element of z , according to the one-to-one mapping $z = f(t)$. Education directly determines skill s according to the one-to-one mapping $s = h(z)$. We are assuming here that there is no direct impact of the trait on wage. Skills impact wage as above. Serially composing gives $w = q(s) = q(h(z)) = q(h(f(t)))$. Thus, in this very special case, one can estimate the effects of skills using direct measures of s if they are available or using the indirect measures z or t . There is no misspecification in this highly restrictive case. If we live in a world where one characteristic such as general intelligence g predicts education which itself predicts skills, then either skills or their proxies can be incorporated in estimation. The econometrician might have data on skills, education, and characteristics. Only one is required.

We turn now to a slightly more general case: unique intelligence plus direct impact of characteristics on skills. The model in this case is as above, except now $s = h(z, t)$. In this case, serially composing gives $y = q(s) = q(h(z, f^{-1}(z)), f^{-1}(z)) = q(h(f(t), t), t)$. Thus, in this special case as well, one can estimate the effects of skills using direct measures of s if they are available or using either of the indirect measures, z or t . There is no again misspecification in this also highly restrictive case. If we live in a world where one characteristic such as general intelligence g predicts education which itself predicts skills, then either skills or their proxies can be incorporated in estimation. The missing element in both of these special cases is the multidimensionality of intelligence and worker characteristics.

Turning now to this more general case with multidimensional intelligence and characteristics, the model is as above, except that now all of the vectors t , z , and s are potentially multi-dimensional. In this case, there is a clear possibility of misspecification. To see this, let there be two characteristics (t_1, t_2) . z is a scalar, with $z = f(t_1)$ as above. There are two skills, (s_1, s_2) . $s_1 = h(z, t_1)$ as above. $s_2 = \eta(t_2)$. In this situation, an estimate of $q(s)$ using only z would be misspecified, as would an estimate using only t_1 . Estimation using z and t_2 or t_1 and t_2 or direct measures of skills would be properly specified.

The main implication of this section's framework is that skill and education are not equivalent. This has several corollaries. First, data on skills, traits, and intelligences are needed in order to estimate outcomes such as the urban wage premium. Second, estimates of disaggregated urban skill premiums obviously require skill data. Third, data on skills also allow the estimation of the impact of agglomeration on skill development. In all three cases, it is clear that data on skills has the potential to be very useful. The remainder of the paper will build on these conclusions by setting out a procedure for estimating worker skills and by estimating a model of skill development.

3. DATA

The previous section deals with theoretical issues involved in the measurement of traits, intelligences, and skills. This section will be more applied. It will consider the measures that are actually

available, and it will discuss their use in light of the theoretical framework developed above. We will focus on U.S. data.

It is natural to begin with the standard approach, where education is treated as being identical to skills. Education variables are available in individual worker level datasets most commonly used in urban and regional economics, including notably the Census and the National Longitudinal Survey of Youth 1979 (NLSY79). Since the geocoded NLSY79 reports the College Federal Interagency Committee (FICE) codes of colleges and universities respondents attended, it is possible to go further by evaluating the quality of the institution of workers who went to college. This can be done by matching the institution's FICE code to the selectivity categories reported by Barron's Profiles of American Colleges. This procedure still ranks all graduates equally, but now only within a college or university.

Measures of traits and intelligences are much harder to obtain. While the readily available Census does have data on family circumstances, age, and so on, it does not have variables that capture relatively stable characteristics of workers that contribute to skill formation.⁸ The NLSY79 is a much richer resource with information on multiple traits and intelligences. Respondents in the NLSY79 were administered the Armed Forces Qualification Test (AFQT), which is generally agreed to capture cognition. In addition, the NLSY79 includes several measures of traits and abilities that capture aspects of social adjustment and interaction. One of these is the Rotter (1966) Scale, administered to respondents in 1979. The Rotter Internal-External Locus of Control Scale is designed to measure the extent to which individuals believe they have control over their lives through self-motivation or self-determination (internal), as opposed to the extent that the environment (i.e., chance, fate, luck) controls their lives (external). This measure of one's sense of self-control has been shown to be correlated with the individual's social skills (Lefcourt et al 1985). NLSY respondents were also administered the Pearlin Mastery instrument in 1992, which is related to Rotter's locus of control. We rescale the Rotter Control Scale and the Pearlin Mastery Scale scores to be positively oriented, so a larger value indicates a better adjusted personality.⁹ The Rosenberg Self-Esteem Scale is a personality assessment administered in 1980 of perceived self-esteem, describing a degree of self-approval or disapproval (Rosenberg 1965). All three of these measures are calculated from responses to psychometric tests. Sociability is the only one that is not test-based in that it comes from a respondent's direct response to an interviewer asking whether the respondent was extremely or somewhat shy or outgoing at age 6. To make this measure comparable to

⁸ The closest measure of a trait is a disability indicator (physical or mental condition impairing work or mobility).

⁹ This means that in all discussion to follow and in all tables, we are using an inverse of the standard Rotter measure of the locus on control.

the other measures that are oriented on a positive scale, we created a Sociability indicator equaling one if a respondent was not extremely or somewhat shy, and zero otherwise.¹⁰

The NLSY79 thus includes data on worker traits and intelligences, as well as data on education.¹¹ These are all part of the skill development process, but they are not themselves measures of skills. The previous discussion of skill development makes a strong case for the value of direct measures of skill. Such measures can be helpful in understanding the urban wage premium, and they are essential to computing more disaggregated urban skill premiums.

This leads naturally to the question: given the absence of skill data, how can one directly address skills? One approach is to infer skills from the occupations that workers pursue. The motivation for this hedonic imputation procedure is straightforward: there is great variation in skills among graduating students, and market outcomes can refine skill attributions. Slightly more formally, hedonic attribution is based on labor market matching. In a frictionless hedonic equilibrium, markets assign a worker with skill level s to activity a through the mapping $a = g(s)$. If the mapping is invertible, then a worker carrying out job a has skill $s = g^{-1}(a)$. In the notation of the previous section, in research on agglomeration, when there is an invertible skill assignment mapping, we have $q(s,n) = q(g^{-1}(a),n)$. This allows estimation of a well-specified model if the econometrician can identify activities and can map activities to skills.

In the next section, we will implement a hedonic attribution using data from the NLSY79 and the DOT. The NLSY79 reports worker occupations. The DOT characterizes the skill requirements of occupations. Matching the DOT with the NLSY79 allows the characterization of worker skills. The period our study covers coincides well with information from the 1991 Revised Fourth Edition DOT, since information in this revision were collected between 1978 and 1990. The revised Fourth Edition updated 2,453 occupations out of the total of 12,742. Occupational definitions in DOT are the result of comprehensive studies by trained occupational analysts of how jobs are performed in establishments across the nation and are composites of data collected from diverse sources. There are 44 different job characteristics available in the DOT. Using the textual definitions of the variables, we identify three broad skill categories in the DOT data for our analysis. We will work primarily with indices for

¹⁰ These measures have been used previously: the AFQT and/or its components to capture cognitive ability (Neal and Johnson (1996) and Heckman, Stixrud, and Urzua (2006), among many others); the Rotter to capture personality traits or non-cognitive ability (see the various studies listed in Table 1 of the survey by Bowles, Gintis and Osborne (2001) and more recently Heckman, Stixrud, and Urzua (2006)); self-esteem (Murnane et al 1997); and Sociability (Borghans, ter Weel, and Weinberg 2007). We include all these measures in our analyses as the quality and amount of information may possibly vary from measure to measure.

¹¹ Note that these measures are assessments performed at either late adolescence (AFQT, Rotter, Rosenberg) or childhood (Sociability). None of them is calculated during the adult working years of our sample. Thus, despite its richness compared to the Census, we are unable to say much about the impact of urbanization on multiple stages of the process of skill formation.

cognitive, motor, and people skills created using principal component (factor) analysis. The indices are also re-scaled to have a mean of 1 and a standard deviation of 0.1.

The cognitive index is constructed through factor analysis of seven DOT cognitive skills. The skills capture the complexity of the job in relation to data; educational development level in reasoning, mathematics and language for the job; and general intelligence, verbal, and numerical aptitudes. A high value on this cognitive index indicates that substantive complexity is involved in carrying out the job. Similarly, we construct a motor skills index from nine DOT variables. These variables capture the complexity of the job in relation to things; aptitudes for manual dexterity, finger dexterity, motor coordination, eye-hand-foot coordination, spatial and form perception, and color discrimination; and adaptability to situations requiring attainment of standards. A higher value on the motor skills index indicates a job with greater manual demands. Finally, we construct a people skills index based on four DOT measures that relate to the people skills involved in an occupation. These variables capture an occupation's requirements of "adaptability to dealing with people beyond giving and receiving instructions," if an occupation requires direction, control, and planning, and if an occupation requires exerting influence.

This hedonic imputation of skill is based on occupation level evaluations of the skill content of work and the maintained hypothesis of a hedonic equilibrium that matches workers' bundles of skills to the skill requirements of occupations. The ideal, of course, would be to observe skills at the individual worker level. In applications such as measuring an urban skill premium, the potential problem is that errors in the attribution of skills could be correlated with regressors such as city size. Bacolod et al (2009a) address this through estimating worker fixed effects in a panel and by including additional controls to attempt to eliminate as much unobserved heterogeneity as possible. The specific controls included are based on the selectiveness of the college or university attended and abilities and traits that could potentially be associated with wage.

What alternatives might be possible? One approach would be to ask workers to assess their skills. Another would be to for some sort of skill auditor to evaluate worker skills. The question that arises for both would be: are these evaluations more accurate than the evaluations of the market? It seems to us that it is not certain that they are. In any case, neither Census nor NLSY nor the Panel Study of Income Dynamics have such direct evaluations of skills. This means that any possible advantage of the evaluation of skills at the individual worker level (which would be costly) must be weighed against the disadvantage of losing the precise estimation that is made possible by the relatively large sample sizes of these standard data sources.

Appendix Table A1 details the sample in our data. Our NLSY79 worker sample includes respondents who worked in the last year, with non-missing hours, and whose occupational codes were

merged with DOT information using the crosswalk from the National Crosswalk Service Center. For reasons that will become more evident below, we include only worker-years when workers are aged 25+.

4. ESTIMATING MODELS OF SKILL DEVELOPMENT

The Spatial Allocation of Traits and Intelligences

Section 2 lays out the case for constructing measures of worker skills that are distinct from education. Section 3 lays out how the measures have been constructed. This section will discuss the results of estimating models of skill formation, as depicted in the Figure 1 and in the left half of Figure 2.¹² The heart of the section -- and of the paper -- will be the estimation of models of the roles of education and cities in skill development.

The measures of traits, intelligences, and skills that we will employ in these models have been used little -- in some instances, not at all -- in the urban economics literature. We will therefore begin the section by looking at the spatial allocation of these measures. Table 1a describes the spatial pattern of AFQT, Rotter, Pearlin, Rosenberg, and Sociability. It is worth re-iterating that Sociability is constructed quite differently from a survey of self-responses rather than a psychometric test and reference to age 6 rather than to adolescence. We adjust all four of these measures so that they are positively oriented (more is better) and range from 0 to 1. The table computes the various measures for MSAs with fewer than 500,000 inhabitants (small cities) and for those with more (large cities). The table reports both totals and values for selected individual occupations.

The key pattern that the table illustrates is that there is relatively little difference in these measures between large and small cities. Beginning at the bottom of the table, the overall average level of AFQT is slightly larger (less than 2%) in the smaller cities. For Rotter, the means are almost identical in small and large cities. Pearlin and Rosenberg have slightly larger values in larger cities at the mean and at the 90th percentile. For Sociability, the mean value is 10% larger in large cities than in small.¹³ The pattern for individual occupations is similar; mean values are not significantly different between small and large cities.¹⁴

Table 1b describes how migration between small and large cities might impact the spatial allocation of traits and intelligences. Specifically, it looks at the values of AFQT, Rotter, Pearlin, Rosenberg, and Sociability for two sorts of "stayers" (small-always and large-always) and two sorts of

¹² The relationship of skills to productivity -- the right half of Figure 2 -- is considered in Bacolod-Blum-Strange (2009a).

¹³ We have also computed the 10th and 90th percentile values of the five measures. The extremes of the distribution are not significantly different between small and large cities.

¹⁴ See Nelson (1942) for additional evidence on intelligence differences between urban and rural populations, and Gist and Clark (1938) on evidence that migrants from rural to urban areas have higher intelligence measures.

"movers" (small-to-large and large-to-small). Looking at the totals, an interesting pattern emerges. Movers, both small-to-large and large-to-small, tend to have higher values of AFQT than stayers. While the differences are not statistically significant, the mean AFQT is smallest for those who remain in small cities: 13% less than large-to-small movers, 9% less than small-to-large movers, and 7% less than large city stayers. For Rotter, Pearlin, and Rosenberg, the differences in the totals are small and statistically insignificant. A closer examination by individual occupations shows this may be due to occupation-level heterogeneity in the spatial distribution of these measures. For instance, small-always teachers, personal service, and admin support workers have the least Rotter than movers or large-always stayers. On the other hand, small-always scientists, nurses, and technicians have the highest Rotter than movers or large-always stayers. The pattern in spatial allocation of Sociability is as for the AFQT, with higher values for movers of both kinds and the lowest value for stayers in small cities (43% less than small-to-large movers). Taken with Table 1a, Table 1b's results are only weakly suggestive of selection of intelligences and traits into larger cities.

Reduced Form Relationship Between Traits, Intelligences, and Skills

Figure 2 depicts a relationship between traits, intelligences, and skills that has both a direct channel and indirect channels that operate through education and urbanization. To estimate the total direct plus indirect relationship in a reduced form model requires the estimation of

$$S_{it} = a_1 T_i + a_2 X_{it} + e_{it}. \quad (1)$$

S_{it} is the skill level of the i th worker at time t .¹⁵ As described above, we work with indices of cognitive, people, and motor skills constructed from factor analysis, with mean 1 and standard deviation 0.1. T_i is the vector of traits and intelligences (AFQT, Rotter, Pearlin, Rosenberg, Sociability; hereafter just "traits") for the i th worker. X_{it} is a vector of other covariates for worker i at time t , including an intercept term, age, age squared, gender, race, a marital status dummy (worker is married or remarried), and the number of children at year t . Some of the measures are not reported for some workers; we therefore include "missing variable" indicators for AFQT, Rosenberg, and Sociability. Both Rotter and Pearlin are reported for all the workers in our sample. In this specification, we pool together all worker-years to estimate the reduced form manifestation of cognitive, motor, and people skills from traits. We estimate the skills equations jointly via feasible generalized least squares (FGLS) to take into account correlation in errors across the skills. We also include controls for urban status in 1979 to condition on early

¹⁵ Note that any error in skill attribution does not introduce bias in this model and others to follow.

urbanization (a dummy variable for a worker who resided in 1979 in an MSA with population of 500,000 or greater). In addition to estimating a pooled model, we also estimate equation (1) separately for large and small cities and separately by educational attainment in order to get at the impact of urbanization and education on the manifestation of worker skills.

The results are presented in Tables 2a and 2b. Table 2a presents the total and small/large MSA models. It is immediately apparent that traits are positively related to skills. This is not at all surprising. Beginning with the full sample estimates at the left of Table 2a, measures of personality, self-esteem and social abilities are all highly predictive of people skills. Higher levels of these traits also translate to greater cognitive skills. Cognitive ability as captured by the AFQT is also positively predictive of people and cognitive skills. In contrast, it is negatively predictive of motor skills.¹⁶

The relationships of skills to other controls are standard and expected. Cognitive and people skills are increasing in age at a diminishing rate, while physical skills are declining in age. Women have more cognitive and people skills (three and four standard deviations more, respectively) and lower levels of motor skills (one standard deviation less). Conditional on multiple measures of abilities, Blacks have slightly higher levels of cognitive and people skills (less than one-half standard deviation) and less motor skills compared to whites. Married workers have one standard deviation higher levels of cognitive and slightly less than one standard deviation higher people skills. However, married workers are not significantly different from singles in motor skills. Cognitive and people skills are diminishing in number of children, while motor skills are increasing. These magnitudes are not large, however. Having one child is related to a decline of less than one standard deviation.

The relationship to the urban variables is consistent with various ideas in the agglomeration literature regarding skills and cities. Urbanization is included in two ways. The first is the control for early exposure to urbanization in 1979. This is included in the pooled model, and in all the models that follow. Being in a large MSA at the beginning of the period is significantly and positively related to high cognitive skills, by nearly half a standard deviation more. It is insignificant in its relationship to motor and people skills. The result that a worker's urban status in 1979 exerts a continuing effect on the worker's cognitive skills is worth considering in some detail. Learning is a crucial source of agglomeration economies, and it has been considered in numerous papers, only a small subset of which are listed in the Introduction. Learning is more than crucial in developmental psychology; it is the whole field. And the field is clear that a substantial amount of learning takes place at early ages. As discussed above, traits are stable, and are not much changed beyond early childhood. Abilities continue to develop through adolescence, but they become relatively set in early adulthood. There is certainly continued

¹⁶ A similar relationship emerges in a model where we do not control for urbanization in 1979.

learning through life, but a lot of really important learning takes place early in life, a fact that has become increasingly apparent to labor economists (i.e., Heckman and Cunha (2007) among others).

It is somewhat striking that although learning is a first-order issue in urban economics, there has been relatively little attention paid to the impact of agglomeration on school outcomes. The attention that has been paid is mostly in the form of indictments of central city schools, an issue that conflates the selection of families into locations, big-city political economy issues, and the possibility of an influence of agglomeration on learning. An interesting paper by Gibbons and Silva (2008) is an exception. It shows a positive effect of density on pupil attainment in a panel estimates, using compulsory transitions between primary and secondary schools to achieve identification. Our paper's estimates the effects of urban status in 1979 are related in showing a positive impact of early agglomeration.

The second way that we consider urbanization is to separately estimate skill manifestation models for small and large cities. The results of this estimation are reported in the two panels on the right side of Table 2a. The relationship between traits and skills clearly varies between large and small cities. Pearlin, Rosenberg, and Sociability all have significant negative relationships with the development of motor skills in large cities and insignificant relationships in the small ones. For Rotter, there is a positive relationship with motor skill development in small cities and an insignificant relationship in large ones. This suggests that small cities enhance the development of motor and manual skills particularly for individuals with better social abilities and well-adjusted personalities. One possibility is that there are more opportunities for youth in the development of their manual coordination in small-town settings. Meanwhile, personality and social abilities are associated with a higher level of cognitive skills in large cities than in small cities. With respect to people skills, a personality with a better sense of control over one's environment (Rotter) leads to more than one standard deviation higher development of people skills in a large city but not in a small city. Higher self-esteem (Rosenberg) also gets deployed to better people skills in a large city (by more than one-half standard deviation), while self-esteem has zero effect in a small city. The other two personality traits (Pearlin and Sociability) are significantly related with people skills in both large and small cities, but are greater (two standard deviations more) in small than in large cities. These results are all conditional on where one was living before age 25 (respondents were aged 14-21 in 1979), so we are comparing skill manifestation in large versus small cities conditioning out early exposure to urbanization. Finally, the relationships between skills and the other controls (for example, age, race, and marital status) are substantially different in small versus large cities. This suggests that workers in small and large cities are different, and that taking into account worker selection into small versus large cities may change the relationship between traits and skills. To summarize somewhat roughly, Table 2a suggests traits are more developed in urban areas towards better cognitive and people skills. Motor skills seem to be better enhanced in small cities.

Table 2b considers the impact of a worker's education on skill manifestation. As noted above, the relationship between abilities and skills also varies by education even conditional on urban status in 1979. For instance, higher levels of cognitive ability as measured by AFQT translate to higher cognitive skills across all education levels. An improvement of one percentile on the AFQT translates to 2.4, 8.5, and 6.9 standard deviations more cognitive skills for less than high school, high school, and college graduates, respectively. Higher AFQT is also deployed as better people skills for workers with less than high school (2 standard deviations more for every AFQT percentile point) and for high school graduates (5 standard deviations per AFQT percentile). However, higher AFQT translates to less people skills for workers with college-plus education (2 standard deviations less per AFQT percentile). Rotter for college-plus workers is insignificant across all skills. In fact, the deployment of social ability and personality traits into skills is most pronounced and significant for high school graduates. This finding is perhaps consistent with the GED puzzle in the labor economics literature. Heckman and Rubinstein (2001) first show that high school dropouts who earn their high school degrees via passing the General Educational Development (GED) exam have the same achievement test scores as high school graduates, but earn on average the wages of dropouts. Heckman, Stixrud and Urzua (2006) explain that the poor labor market performance of GED recipients is due to their low levels of non-cognitive skills, lower even than dropouts. Our finding that the deployment of interactive traits into skills is most significant for high school graduates is consistent with this GED literature, since the high school graduates in our data include both those who earned their high school degrees through formal schooling and those who pass the GED exam. The labor literature has established that it is for this particular group that differentiation in non-cognitive traits matters.

The Relationship Between Traits and Abilities and Urban Status and Education

As discussed above, there are two indirect channels by which traits can impact skills. Denote the education of worker i at time t by E_{it} . As above, continue to denote the urban status (large or small) by U_{it} and the traits by T_i . If the vectors X_{it}^E and X_{it}^U denote the covariates that impact, respectively, education and urbanization, then we estimate these indirect channels by estimating the following equations:¹⁷

$$E_{it} = \gamma T_i + \Psi X_{it}^E + v_{it} , \tag{2}$$

$$U_{it} = \beta T_i + \Phi X_{it}^U + \omega_{it} . \tag{3}$$

¹⁷ The previously introduced X includes everything in X^E and X^U .

We could estimate equations (2) and (3) separately as ordered discrete choice models, with E_{it} denoting the highest completed education level and U_{it} denoting progressively larger SMSA size categories. Given our small sample and the later joint estimation with skills, we prefer a more parsimonious estimation strategy. To show that our results are similar across a linear versus discrete choice model, Equation (2) is estimated in two ways, by ordinary least squares (OLS) with E_{it} denoting highest grade completed (years of completed schooling) and by multinomial logit where E_{it} denotes education attainment (less than high school, high school and college). Equation (3) is also estimated in two ways, by OLS and by simple logit (large or small city).

The results are presented in Table 3.¹⁸ First, higher AFQT workers are more likely to live in large cities. A one percentile point improvement on the AFQT is associated with 1.6 to 1.7 percent greater likelihood of living in a large rather than a small city. Second, workers with better personalities and more social ability are also more likely to live in large cities. A one standard deviation increase relative to the mean in control mastery (Pearlin) and self-esteem (Rosenberg) increases the probability of living in a large city by 1 to 1.5%.¹⁹ Being outgoing (Sociability=1) is also associated with 1.3 to 1.4% higher probability of living in a large city. Note, too, that the coefficients on AFQT, Rotter, Pearlin, Rosenberg, and Sociability are very similar in both significance and magnitude across the nonlinear logit estimation and OLS. Third, married workers are 2.6% significantly less likely to live in large cities than in a small city. Having one more child is also associated with 3% less likelihood of living in a large vs. small city. In our later estimation, we will use marital status and number of children as exclusion restrictions.

With respect to the relationship between traits and schooling, as is well known, AFQT is positively associated with educational attainment. Our OLS estimates show that a one standard deviation improvement in AFQT (a 10 point increase in the percentile) is associated with 0.5 more years of schooling.²⁰ Second, better personality, social ability (self-esteem, control) and sociability traits (is outgoing) are also associated with more years of schooling. Third, the multinomial logit results indicate that individuals with higher AFQT and better social traits are less likely to graduate from high school relative to dropping out. Finally, we find that early exposure to urbanization makes it less likely for one to graduate from college relative to dropping out of high school.

¹⁸ The results are the same in models that do not control for urban status in 1979.

¹⁹ The means and standard deviations are reported in Appendix Table A1.

²⁰ Cascio and Lewis (2006) estimate that an additional year of schooling raises AFQT of minorities in the NLSY79 by 0.31 to 0.32 standard deviations. Although this estimate is in the opposite causal direction (the effect of schooling on AFQT identified using a regression discontinuity design based on birth dates and schooling start dates), our estimate of the relationship between schooling and AFQT is broadly consistent.

Overall these results show us that traits and abilities are potentially endogenous to location choices and to human capital investment decisions. All measures of cognitive and social traits are significant determinants of schooling and the choice of living in a large vs. small city.

Structural Estimates of Direct and Indirect Effects

An alternative approach to estimating the direct and indirect channels of the relationship between traits and skills is to estimate the three channels jointly. This framework is similar to other estimation strategies in labor economics that endogenize schooling choices (i.e., Heckman, Stixrud and Urzua 2006), although the outcomes of interest in those papers are labor market outcomes such as wages and employment rather than skills. This approach involves estimating the system:

$$S_{it} = \alpha_0 E_{it} + \alpha_1 T_i + \alpha_2 U_{it} + \Gamma X^S_{it} + u_{it} , \tag{4}$$

$$E_{it} = \gamma T_i + \Psi X^E_{it} + v_{it} , \tag{5}$$

$$U_{it} = \beta T_i + \Phi X^U_{it} + \omega_{it} . \tag{6}$$

X^S includes covariates relevant to the skill equation and are assumed to be exogenous. In jointly estimating equations (4)-(6), this approach formalizes the endogeneity of education and urbanization in skill manifestation in addition to estimating the relationship between traits and skills. The direct effect of traits on skills is captured by the parameter α_1 . The indirect effect of traits that works through education is captured by $\alpha_0 * \gamma$, while the indirect effect that works through urbanization is captured by $\alpha_2 * \beta$.

Usually in a system of linear simultaneous equations such as above, there is some overlap in the exogenous variables X^S , X^E , and X^U . However, to identify this system, they cannot perfectly overlap. To see this, one can substitute equations (5) and (6) directly into equation (4) so that the skills equation is a function only of exogenous variables. If the X 's perfectly overlapped in this “reduced form” version of the skills equation, none of the individual structural parameters are identified. To identify the skills equation, we need at least two excluded exogenous variables since there are two endogenous variables. In order to separately identify γ from β , X^U also cannot overlap perfectly with X^E .

Exclusion restrictions are thus necessary in order to estimate equations (4)-(6) jointly—either factors that determine schooling but not urbanization, or factors that determine the location decision but not schooling. We use marital status and the number of children affecting the urban decision but not the education decision. The assumption that current marital status and number of children affects location decisions but has no direct effect on education can be questioned, of course. The exclusion restrictions

are reasonable, however, as workers in our sample are all over age 25. Most workers have completed their schooling by age 25, and thus, marital status and number of children at age 25 and older are excludable as determinants of past schooling decisions. Meanwhile a single worker is more likely to be in an urban environment for a larger access to the marriage market or other types of amenities that singles consume. A worker's number of children is also a potential determinant of the urban decision, as workers with more children are possibly more likely to live in smaller cities with lower cost-of-living and cheaper access to good public schools. We estimate the entire system above by FGLS.

The estimates are reported in Table 4. As expected, urbanization has a significantly positive direct impact on cognitive and people skills and negative on motor skills. The same holds true with education. Table 5 presents the calculations of the direct and indirect estimates. Interestingly, the indirect effect via education of traits on skills is greater than the direct effects. In other words, schooling magnifies both cognitive and social traits in the deployment of cognitive and people skills, once we condition on urban status in 1979. Furthermore, urbanization also has an indirect effect on the deployment of skills but not as substantial as education.

Finally, it is worth recalling that we also condition on urban status in 1979. Table 4 suggests that urbanization during youth has a significant and continuing effect on skills through its effect on education and predictive power on current urban status. Living in a large city in 1979, when workers were still aged 14 to 21, is associated with 0.12 fewer schooling grades. Being raised in a large city also makes it 21% more likely for a worker to currently be in a large city.

Overall, these estimates are consistent with the framework we laid out above. There is a significant relationship between traits and skills. Some of this works directly through the direct impact of traits on skills. However, there is also a substantial indirect effect that works through urbanization and education.

Movers and Stayers

The final reported results (Table 6) are computed using the mover – stayer breakdown discussed above. The table reports the marginal effects from a multinomial logit model of moving between small and large cities. AFQT is positively associated with both kinds of moves, small-to-large and large-to-small. The effect is significantly larger (more than doubled) for the small-to-large move, however. A one percentile improvement on the AFQT is associated with 23.3% higher likelihood of a small-to-large move vs. staying in small cities while only 9.6% higher likelihood of a large-to-small move vs. staying in small cities. This has two implications. First, the net effect is towards higher AFQT in large cities, the sort of selection effect that has been noticed previously (i.e., Combes et al, 2008). Second, both types of movers—even those who move from large to small cities—have higher levels of AFQT. This result, new

to the literature, suggests that the way that sorting might work in a dynamic framework is not simply for the most able to move to the biggest cities.

Taken as a group, the results for the four measures of social traits have a somewhat similar pattern, but not an identical one. The pattern for Rosenberg (self-esteem) and Sociability are exactly the same as for AFQT: a net selection effect towards big cities, with more able workers making both types of moves. A worker with mean value of Rosenberg (0.8) is 19% more likely to move from small-to-large vs. staying in small cities and also 9.4% more likely to move from large-to-small. Being outgoing (Sociability) raises the probability of moving small-to-large and large-to-small by 7.7% and 5.1%, respectively, relative to staying in small. The pattern for Rotter exhibits the same net selection effect towards large cities, but the pattern for ability levels of movers is different. There is a positive marginal effect associated with Rotter for small-to-large moves, but the effect is insignificant. There is a negative and significant marginal effect associated with Rotter for large-to-small moves. A worker with mean Rotter is 8.3% less likely to move from large-to-small. The only exception to the basic pattern of net selection towards large cities and of more able workers moving is for Pearlin (self-mastery). A worker with mean value of Pearlin (0.72) is not significantly more likely to move from small-to-large, while the same worker is 12.3% more likely to move from large-to-small vs. staying in small.

Earlier we showed workers with higher cognitive and social abilities are more likely to live in large cities, conditional on early urban status. The analysis in Table 6 shows these more able workers are also more likely to have moved—including moves from large to small cities. Thus, any framework that attempts to take into account sorting cannot be a simple story of the most able workers moving towards the biggest cities.

5. CONCLUSION

This paper begins with the observation that skill does not equal education. The paper is devoted to clarifying the relationship of skill to education and what this means for the urban and regional economic analysis of skills. The bottom line is that education is a part of the process that determines skills, a crucial part. However, a worker's prior abilities and traits matter too. With contributions from education and also from agglomeration, traits and intelligences determine skills.

Fortunately, it is possible to characterize worker skills using occupation level data on the skill requirements of jobs such as the DOT and O-NET. If markets for skill clear in a hedonic sense, then workers are matched to jobs that require the skills that they possess. This approach allows one to consider the spatial distribution of skills (Bacolod-Blum-Strange, 2009a and 2009b) and to consider the impact of agglomeration on the hedonic prices of skills (Bacolod-Blum-Strange, 2009a).

This is an approach that has the potential to contribute to the solution of other important questions in urban and regional economics. For instance: what is the effect of the local level of human capital on growth and productivity? Since Rauch's (1993) seminal paper establishing a strong relationship between wages and rents and the percentage of an MSA's workers with college educations, there has been considerable attention focused on the endogeneity of education. This concern is well-placed. Another concern -- one that has largely escaped attention -- is that education is not synonymous with skills. Theories of agglomeration based on matching do not simply focus on matching workers differentiated by their education (i.e., college or not). They focus on matching workers with different skills (i.e., ability to manage). Theories of agglomeration based on learning certainly do not focus on an increase in the ease of acquiring a college degree. They focus on learning job skills from nearby workers. It is therefore worth considering whether it is the presence of multi-dimensional skills that contributes to productivity and growth. Similarly, local innovation has been shown to be related to the presence of educated workers and to universities themselves. In this case, as well, a largely unasked question is whether it is local skill that impacts innovation.

This discussion has focused on the implications of the measurement of worker skill for the various outcomes that are believed to be impacted by agglomeration. A second contribution of the traits-abilities-skills framework is that it suggests a way of thinking about the role of agglomeration in skill determination. It is already understood by researchers in education that intelligences and traits are associated with skills, and that education contributes to this relationship. It is also understood by researchers in urban and regional economics that agglomeration can contribute to skill development as well.

The construction of skill measures by hedonic attribution allows the formal analysis of this relationship. This paper shows that agglomeration is related to the manifestation of skills from traits and intelligences for both cognitive and people skills. We do not find evidence of such a relationship for motor skills. In addition, for both cognitive and people skills, there is evidence of sorting, where more skilled workers disproportionately choose large cities.
